

Soil biomass

1. Soils are a living resource

Soils are home to about 25% of the planet's biodiversity [1],[2]. A huge proportion of living organisms spend a more or less important part of their life cycles in soils. These include a myriad of micro-organisms (e.g. bacteria, fungi, protozoa and nematodes) and mesofauna (e.g. acari and springtails), as well as the more familiar macro-fauna (e.g. earthworms and termites). They interact with one another and with the various plants, micro-organisms and animals of the ecosystem, forming a complex web of biological activity (See [Soil Biodiversity](#) & [Collembola: actors of soil life](#)).

Soils are the foundation of every terrestrial ecosystems: each biome has soils with its own characteristics. They contribute *via* a wide range of services to the sustainable functioning of all ecosystems. Although soil biodiversity differs in tropical forests, savannahs, pastures, tundras, etc., the overall soil biomass remains dominated by the same major taxa: fungi, bacteria and protists (Table 1). [3]

Table 1. Distribution of biomass according to groups of living things in soils. (expressed in Gt C). Of course, the carbon contained in living organisms represents only a fraction of the carbon in soil organic matter (litter, etc...). [Table based on data from Bar-On et al. ref [4]; Open access article distributed under CC BY-NC-ND 4.0 license]

Taxon	Mass [Gt C = 10 ¹⁵ g C]	Abundance
Fungi	12	10 ²⁷
Bacteria	7	10 ²⁹
Protists	1.5	10 ²⁷
Arthropods *	0.2	10 ¹⁸
Annelids	0.2	10 ¹⁸
Nematodes **	0.01	10 ²¹

* Biomass from all terrestrial arthropods

** Considering that soil nematodes represent about half of the total nematode biomass in the biosphere

2. A world dominated by Fungi and prokaryotes

The total soil microbial biomass of 20 Gt C is mostly fungal biomass (≈ 12 Gt C, a value to be compared with that of marine fungi ≈ 0.3 Gt C) [4]. The global fungal biomass estimate is based on two contributions, one from soil fungi (there are approximately ≈ 100 meters of fungal hyphae per gram of soil) [4], and the second from plant-associated mycorrhizal symbionts:

- Ectomycorrhizae are also fungal symbionts of plants, but they do not penetrate the cell walls of their hosts. They are found primarily in boreal forests and many temperate forests (e.g., those dominated by *Pinus*) [5]. The total biomass of ectomycorrhizal fungi is roughly ≈ 0.2 Gt C;
- Arbuscular mycorrhizae are fungal symbionts that penetrate the cell wall of their host cells. Plants associated with this type of fungi predominate in deserts, grasslands, shrublands, and tropical forest ecosystems [6]. The biomass from arbuscular mycorrhizal fungi accounts for approximately ≈ 0.15 Gt C.

Of the ≈ 8 Gt C of prokaryotic biomass in the soil, most is due to bacteria (≈ 7 Gt C) and only about $\approx 0.7\%$ is due to archaea (≈ 0.5 Gt C) [4]. Interestingly, soil is one of the top 5 habitats for bacteria and archaea (3×10^{29} cells), the others being: deep oceanic subsurface (4×10^{29}), upper oceanic sediments (5×10^{28}), deep continental subsurface (3×10^{29}), and oceans (1×10^{29}) [7].

Protists are eukaryotic organisms that are neither animals, plants, nor fungi. Most of them belong to little-known groups of parasites, symbionts, and predators of all kinds; with the exception of the Metazoa group, protists are found in virtually all groups of Eukaryotes [8]. The biomass of soil protists amounts to ≈ 1.5 Gt C.

Earthworms are the most conspicuous soil species; their density is highly variable across biomes and depth. Biomass estimation is ≈ 0.2 Gt C. About half of the biomass of nematodes, an animal phylum containing both marine and terrestrial species, is found in soil (≈ 0.01 Gt C).

Biomass of terrestrial arthropods (≈ 0.2 Gt C) is distributed in almost equal amounts in the canopy, litter, and soil *stricto sensu*.

3. Depth distribution of soil biomass

Soil biomass is distributed in the various horizons from the soil surface, where the litter is located, to several meters depth. Many soil faunal biomass data may contain measurements of both soil and litter communities. The total weight of soil is ≈ 400 times greater than the weight of litter (litter weighs ≈ 0.5 kg m⁻², and the relevant soil section weighs ≈ 200 kg m⁻²).

Figure 2. In a soil, most biomass is found in the upper $\approx 10\text{-}20$ cm, but microbial biomass is largely present deeper. [Photo © Michael Dennis Stagg, cc-by-sa/2.0; via geograph.org.uk/p/3046082]

Litter is composed of dead and decaying plant material (mostly leaves and twigs) that have fallen onto the soil (See [The place of soils in the carbon cycle](#)). In addition to decomposing plant material, litter contains microbes and fauna (prokaryotes, protists, fungi, nematodes, annelids and arthropods).

- Plant litter corresponds to about ≈ 80 Gt C.
- Microbial biomass (bacteria, archaea, fungi, and protists) in litter is estimated to be less than 1% of the total mass of organic carbon in litter. This means that the amount of microbial biomass in the litter will not exceed 1 Gt C, which is less than 10% of the total biomass of soil microbes.

Thus, the contribution of litter microbes does not dramatically affect estimates of the total biomass of soil prokaryotes, protists, or fungi [\[3\]](#).

The major part of the biomass from most living organisms is found in the top $\approx 10\text{-}20$ cm of soil. Estimates of soil biomass also include the biomass contribution of litter nematodes and annelids (See [Soil biodiversity](#)).

However, several studies have analyzed microbial biomass (which includes both fungi and other microbes such as prokaryotes) at a deeper depth in forest and other soils. Bacterial cells below 1-meter depth constitute $\approx 15\text{-}\approx 30\%$ of the total amount of bacterial cells in soils: cell densities range from 4×10^7 (forests) to 2×10^9 cells per gram of soil in the top meter of soil to a density of 10^6 to 10^8 cells per gram of soil for 1-8 meters depth.

The deep continental subsurface, which includes the earth's subsurface more than 8 meters below ground level, is dominated by bacteria and archaea. Their quantitative estimation remains very difficult.
