

What is the impact of air pollutants on vegetation?

GARREC† Jean-Pierre, Directeur de Recherche INRA, Laboratoire Pollution Atmosphérique, INRA, Centre de Recherches de Nancy

02-05-2019

Plants are at the forefront of air pollution because they are fixed organisms at the basis of the functioning of terrestrial and aquatic ecosystems. The nature and extent of the impact of air pollutants on plants will depend on the physiological and biochemical characteristics of the affected plant, and the properties of the pollutant(s) encountered. According to the nature of the pollutant, various physiological disturbances can be observed on plants, over areas ranging from the local scale to the entire planet. They will immediately affect ecosystem functioning and in particular plant-insect relationships. They can also have effects on human health, as plants are the source of many food chains.

1. What is a polluted atmosphere?

The atmosphere, the gaseous envelope surrounding the Earth (see [The Earth's atmosphere and its gaseous envelope](#)) contains a number of natural constituents: a mixture of gases (78% nitrogen, 21% oxygen, and also some other minor gases including 1% argon, CO₂, neon, helium, ozone [\[1\]](#), etc.), water (solid, liquid and vapour) and solid or liquid, inorganic or organic particles in suspension (aerosols).

Figure 1. Some of the major air pollutants, their origin (transport, industry, agriculture, biomass, etc.) and their impact on the environment and health. In the case of ozone, we are talking about ground-level ozone generated by pollution near the Earth's surface.

The atmosphere is polluted when the content of some of its natural constituents is higher than normal and/or when it contains new components (see [Air pollution](#); [How does the law protect air quality?](#); [Outdoor air pollution: understanding to inform and prevent](#)). But air pollution is mainly referred to as air pollution when these increases lead to levels of components such that they have harmful effects on the various components of different ecosystems (plants, animals, etc.), on humans (health effects) and on materials [\[2\]](#).

Depending on the type of component considered (Figure 1) [\[3\]](#), these increases may concern very small areas as well as the entire planet. If air pollution has always existed (because of volcanism, fires, for example), it is with the advent of the industrial era that it has become a real problem for the environment and health (see [Air pollution](#); Focus [Birds: flying air filters](#)).

2. Physiological responses of plants

While plants, due to their fixed life and wide distribution, are among the first victims of air pollution, they can also be a source of secondary pollution. During high heat, they emit volatile organic compounds (VOCs) such as terpenes [\[4\]](#), one of the precursor gases of ozone (Figure 1). In cities in the hot regions of the USA, it is recommended not to plant certain trees (pines, oaks, etc.) in order not to increase ozone levels. Plants also emit fine particles (pollens, spores, wax compounds, various particles) which, if they have no effect on plants, can have effects on human health (allergies).

2.1. Penetration of pollutants into plants

Figure 2. Schematic representation of the environment of leaf surfaces. Stomata, located mainly on the surface of the leaves, are the preferred site for the plant's gas exchange with the atmosphere. Among the volatile organic compounds emitted by the plant are many terpenes - α -pinene, β -pinene, isoprene- responsible for summer air pollution, particularly in forest areas and mountain valleys. The size of the cells is in the range of 10 to 100 μ m. [Source J.P. Garrec]

The penetration of pollutants into plants is mainly through the leaves (Figure 2). There may also be a slight penetration through the stems and trunk. Before reaching the leaf, the pollutant will first have to pass through the "boundary layer" which corresponds to the layer of air not agitated in contact with it (Figure 2).

The thickness of this layer depends on the size and shape of the leaf, the presence of leaf hairs (or trichomes) and wind speed. Its thickness is in the order of a few tenths of a millimetre.

During the temporary presence of a pollutant in this boundary layer, many reactions are likely to occur because the incident pollutant will react with:

An aqueous phase consisting of the water film present on the surface of the leaf as well as water bound to the polar groups of the cuticle (see Focus [Between protection and defence: the plant cuticles](#));

A lipid phase consisting of the waxes present within (intracuticular waxes) or located on the surface (epicuticular waxes) of the cuticle (see Focus [Between protection and defence: the plant cuticles](#));

A gaseous phase consisting of the components of the atmosphere and the emissions of the leaf [5].

Depending on the nature of the reactions that will or will not occur at the boundary layer, the concentration of the pollutant that will enter the plant can vary greatly. Some products of these reactions are even more phytotoxic than the pollutant itself [6].

Figure 3. Schematic representation of the decreasing evolution of the concentration of a pollutant from the atmosphere to the inside of the leaf. [Source: J.P. Garrec]

Gaseous pollutants enter the plant like other atmospheric gases (CO₂, Oxygen,...), mainly through stomata present on leaf surfaces. On the other hand, a large part of the organic pollutants will be absorbed mainly by the lipid structure of the cuticle (Figure 2). Only a small part will penetrate the leaf, then diffuse and react between and within the different internal compartments that constitute the apoplast and symplast (Figures 3 & 4).

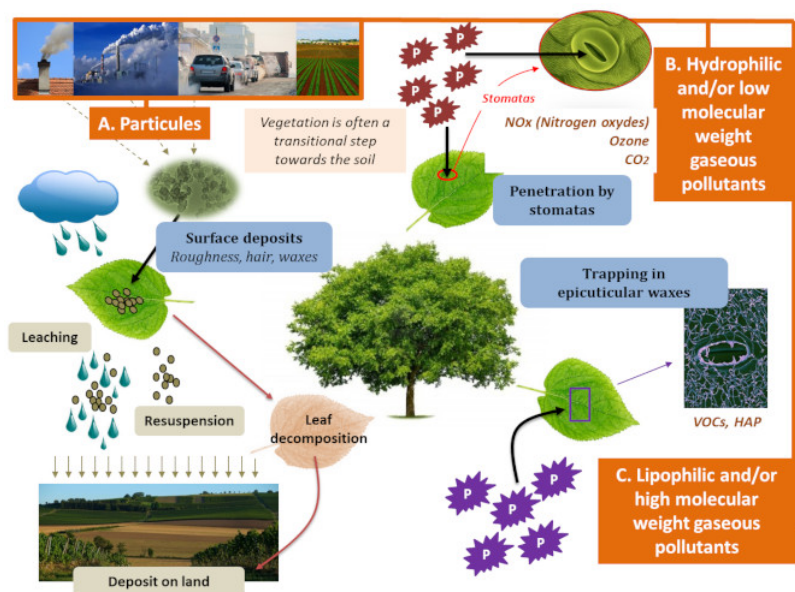

Figure 4. Schematic representation of the behaviour of the various pollutants (gaseous and particulate) towards plants.

Particulate pollutants (organic or inorganic) are first captured by foliar surfaces (thanks to the micro-structure created by the presence of epicuticular waxes, trichomes, etc.), in a size range that is generally between 1 and 10 µm. In forests, this particulate deposition can vary between 280 and 1000 kg per hectare. Subsequently, meteorological conditions such as wind, sun and especially rain (leaching of leaves, dissolution of inorganic particles) influence the characteristics of this deposition (Figure 4). Thanks to the effectiveness of the cuticular barrier, organic or inorganic foliar deposition often causes only a slight penetration of pollutants into the leaves and therefore limit their physiological impacts.

After penetration, the physiological response of plants to air pollution will depend on the two actors involved: on the one hand, the characteristics of the plant and, on the other hand, the nature of the pollution.

2.2. The answer depends on the plant

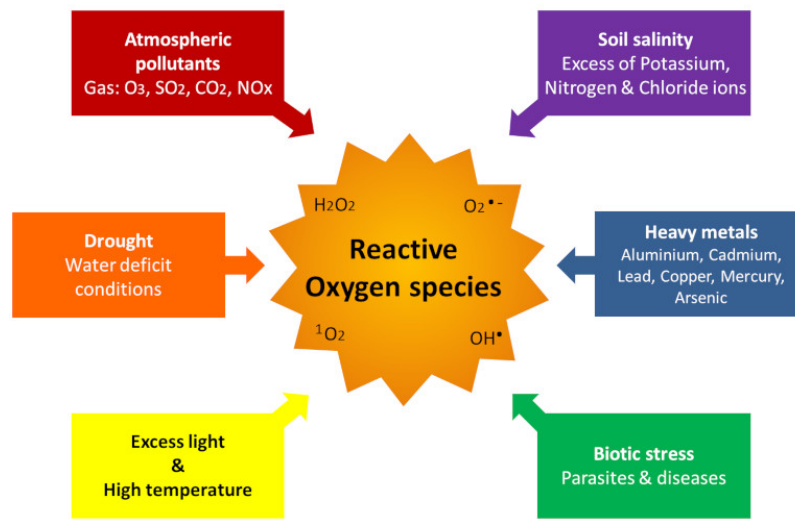

Figure 5. The production of reactive oxygen species (ROS) is a classic defence strategy when plants are subjected to a wide variety of stresses (drought, excess light, attack by pathogens, soil salinity, etc.). This is also the case when they are exposed to air pollutants.

Plants react to air pollution by producing reactive oxygen derivatives. After penetrating the leaves, and as for most biotic and abiotic stresses (see [The fixed life of plants and its constraints](#); [How do plants cope with alpine stresses?](#)), the pollutants will first of all induce an oxidative stress with the production of free radicals (hydroxyl radicals) and reactive oxygen species (ROS) likely to cause damage at different levels (Figure 5) [7]. In particular, these ROS will have three main targets at the cell level: lipids (at the membrane level), proteins (at the amino acid level) and nucleic acids (adduct formation).

At the same time, the pollutant will cause specific stress related to its own physico-chemical characteristics:

Thus, in the case of pollution by hydrofluoric acid (HF), there will be a disruption of the cellular metabolism of calcium (precipitation of calcium in the form of CaF_2).

In the case of pollution with sulfur oxides (SO_2 ...), the reducing properties of this gas will disturb the functioning of the photosynthetic apparatus (degradation of chlorophyll)

Acid rain, on the other hand, causes mineral deficiencies leading to yellowing of the leaves due to rainwater leaching of the mineral elements Ca, K and Mg.

When facing these stresses, the traditional strategy of defending the plant aims to limit the absorption of the pollutant and increase its tolerance to it. It consists in implementing: (a) physical processes, *i.e.* closing stomata, falling leaves...; and (b) chemical and biochemical processes.

These chemical and biochemical factors correspond to:

production of insoluble precipitates (formation of CaF_2 in the case of fluorine pollution);

detoxification by the reduced form emission of the pollutant (H_2S in the case of pollution by SO_2 , NH_3 in the case of pollution by NO_x);

enzymatic degradations by cytochromes P450 and a number of antioxidant enzymes [8],[9]. Non-enzymatic antioxidant compounds such as glutathione, vitamins E and C and carotenoids may also be involved.

When a "pollution stress" is installed, the plant will therefore set up (more or less quickly) processes that will be added to the pool of defence processes already present in the plant. Following the aggression, the plant's resistance to the pollutant will result from the combination of these various processes. For this reason, there is a specific scale of plant sensitivity for each pollutant and for each plant.

Visible and invisible damage. During low pollution and/or when the plant's defence systems are sufficient to limit the

physiological impact of a pollutant, this resistance still has a physiological cost, which is characterized by decreases in size, in yield... We then speak of "invisible damage".

During heavy pollution and/or when the plant's defence systems are not sufficient, irreversible damage appears such as cell death (leaf necrosis, among others). This is referred to as "visible damage" due to air pollution.

Plants react according to environmental conditions. The plant, like all biological systems, is sensitive at the same time to abiotic factors (temperature, humidity, light...) and biotic factors (age, diseases, genotypes...) in its environment. If diseases have a negative impact, other factors can have a positive impact on the plant's response to air pollution. Thus, drought leads to the closure of stomata, which protects the plant, while the increase in CO₂ promotes photosynthesis. The daily evolution of air pollution will also affect the response of plants. This is what field observations show:

During hot weather, high temperatures lead to very high ozone concentrations in the air but at the same time to the closure of stomata. The result is a very low impact of this pollutant on vegetation during these periods. This was observed in the forests during the 2003 heat wave.

During summer periods, ozone concentrations in the air around high altitude forests are high with slight day-night variations. As the high air humidity in these areas leads to a large opening of the stomata, a high impact of the ozone present is observed.

On the other hand, at the level of lowland forests, air pollution is characterized by average ozone concentrations, this time with strong day-night variations. As the air humidity is lower in these areas, the opening of the stomata will be less important: for these two reasons, a lower impact of ozone is observed.

2.3. The answer depends on the pollutant

Figure 6. Appearance of foliar necrosis on vegetation as a function of different air pollutants. Average threshold concentrations as a function of exposure time. [Source: © J.P. Garrec]

Depending on their chemical nature, pollutants are more or less phytotoxic. Laboratory experiments have classified the main air pollutants (at equal concentrations in air) in the following order of decreasing phytotoxicity (Figure 6):

Hydrofluoric acid (HF) > ozone (O₃) > sulfur dioxide (SO₂) > nitrogen dioxide (NO₂)

This classification is only given as an indication because there is a whole range of sensitivity of the different plants for each pollutant. For example, tobacco is very sensitive to ozone but not very affected by fluorine pollution.

In addition to the phytotoxicity of the pollutant, plants response will depend on the dose received (*i.e.* concentration x time). The dose is often calculated from the concentrations of pollutants in the atmosphere. It is the calculation of the flows of pollutants that have actually entered the leaf organs [10] that provides the best information on pollution-damage relationships in vegetation.

Finally, at equal doses, the shorter the application time is, the greater is the pollutant impact. This "peak effect" is usually explained by the fact that, over short periods of time, the plant does not have time to start its defence systems.

3. Symptomatology

Symptomatology analyze the signs or manifestations (symptoms) expressed by plants in response to physiological disturbances induced by air pollutants.

This symptomatology is important because it can be used as a method of bio-monitoring of air quality with plants [11]. This original method makes it possible to detect and estimate levels of air pollutants only by studying the visible (by observing necrosis) or invisible (by biochemical analyses) disturbances they cause on plants.

As the pollutants present around plants are very numerous, it is interesting to classify them, for symptomatological observations, according to the extent of their impact zone: local, regional or global.

3.1. Local pollutants

Local pollutants will have, at the plant level, impacts on at most a few tens of kilometres around their emission sources. These are mainly nitrogen compounds emitted directly from pollution sources (primary pollutants), mainly NO_x (from transport) and NH₃ (from agriculture and transport). These nitrogen compounds are paradoxical pollutants as they are not very phytotoxic but have a strong impact on vegetation:

they have a beneficial fertilizing effect by promoting growth in the first place;

but they have a negative impact over time by causing eutrophication of ecosystems [12], mineral deficiencies, effects on biodiversity (nitrophilic plants are favoured) and a decrease in resistance to various stresses.

Other local pollutants in the air are particulate deposits. It should be remembered that the vast majority of air pollution sources are both emitters of gas and dust (particles). Particulate deposits are composed of an inorganic fraction (heavy metals), but also an organic fraction (PAH, etc...). They include, among other things:

Transport related pollutants. These are organic compounds such as BTX (VOCs in exhaust gases), or inorganic compounds such as platinumoids: Pt, Rh, Pd (catalytic converters), titanium (aircraft engines), etc.

Pollutants related to agriculture following the transfer of plant protection products such as pesticides (herbicides, fungicides, insecticides) into the air during spraying.

Emissions from incineration facilities with in particular organic compounds such as dioxins, furans, PCBs, etc.

All these different particulate pollutants have little or no impact on vegetation, but they cause contamination of the food chains of humans and animals via plants.

For some local pollutants, the impact may be more pronounced. The massive use of more or less biodegradable detergents discharged into the sea leads to water and then air pollution (from the formation by winds of spray loaded with detergents present on the surface) [13]. The deposition of these surfactants on the leaves will then promote the penetration of salt into the plants, causing their subsequent decline and death. Impacts of this particular pollution can be observed on the edges of certain coastal forests around the Mediterranean.

3.2. Regional pollutants

Regional pollutants can have impacts over several hundred kilometres around their emission sources. They mainly include acid deposition, with mainly the presence of H₂SO₄ and HNO₃ in wet or solid deposition. They are secondary pollutants because they are the result of interactions between primary pollutants (SO₂, nitrogen compounds) and ozone [14].

Figure 7. Impact of ozone on tobacco leaves BEL W3. Photo © J.P. Garrec.

Acid deposition has a low impact on plants: yellowing of needles and decrease in tree vitality due to leaching of the ions they induce. On the other hand, ozone is a very phytotoxic gas due to its direct and highly oxidizing effects on the plant's various physiological processes (photosynthesis, respiration, etc.). It is the most worrying pollutant currently affecting vegetation and ecosystems because it causes yield losses of up to 5 to 10%, and the appearance of leaf necrosis (Figure 7) now visible in natural environments. But it also has indirect effects on vegetation because it is a greenhouse gas linked to climate change.

It is now considered that 90% of the yield losses related to air pollution in the plant world come from ozone [15]. However, this observation must be put into perspective for the growth of vegetation in anthropized ecosystems (field crops, etc.): the negative effects of ozone are very often masked by the positive effects on photosynthesis of the increase in CO₂ in the atmosphere (280 ppm before the industrial era compared to more than 400 ppm currently).

Following this significant impact of ozone on vegetation and in order to detect and assess its effects, numerous lists have been drawn up indicating the sensitivity of plants present in different natural or anthropogenic environments (forests, grasslands, field crops, etc.) to ozone, depending on the climatic zones encountered (Western and Central Europe, Mediterranean coast of Europe, etc...) [16].

3.3. Global pollutants

Global pollutants have global impacts. They mainly include CO₂, which is a pollutant linked to the massive use of fossil fuels by transport and industry. CO₂ is a paradoxical pollutant, which will have direct beneficial effects on plant growth via its essential role in photosynthesis. But at the same time, it has indirect harmful effects on plants through the greenhouse effect and the resulting climate disturbances. Other global pollutants include:

Methane or CH₄, a gas produced by digesting herbivorous animals, anaerobic environments such as rice fields;

CFCs and HFCs [17] (used in refrigerators or as solvents);

N₂O (from the massive use of fertilizers in agriculture);

Methyl bromide [18] (used as a disinfectant in sericulture soils)

All these other gases only have an indirect effect on vegetation via their roles in the greenhouse effect. They are also, with the exception of CH₄, ozone-depleting gases with the possibility of another negative impact on plants as a result of increased solar UV-B fluxes reaching the ground.

4. Implications for natural and human ecosystems

4.1. Impacts on ecosystems

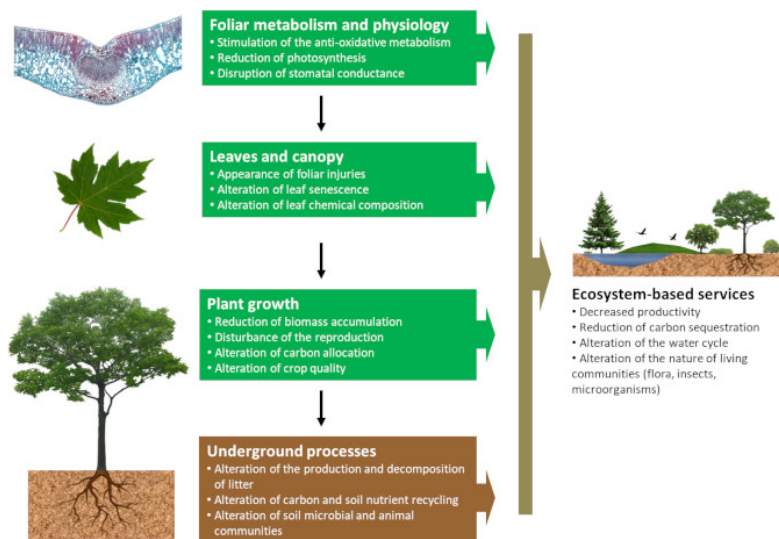

Figure 8. Effects of ozone on vegetation: from plant cells to ecosystems. [Source: © J.P. Garrec]

Plants are the basis for the functioning of most terrestrial and aquatic ecosystems. Physiological disturbances of plants under the impact of air pollution will then cause complex and very varied effects on these different ecosystems (Figure 8). For example, community disruptions resulting from changes in competition between species following the elimination of sensitive species will have an impact on biodiversity, with biodiversity being depleted in most cases.

For a long time, pollution has been considered as responsible for acute toxic effects on ecosystems with sudden imbalances (massive plant mortality). Nowadays, and in our regions, the chronic effects of air pollution on ecosystems have also been observed, with progressive but often equally dangerous changes over time.

The consequences of eutrophication and the acidification of natural environments under the respective effects of nitrogen compound deposition and acid deposition are clear examples of these progressive alterations in ecosystem composition following the impact of air pollution on vegetation. Similarly, ozone -by accelerating the development and ageing of vegetation, and by reducing the vegetative cycle- will reduce the growth of plant species in natural environments with a slow repercussion on the balance of ecosystems.

Ultimately, as they move up the food chain, these slow disturbances eventually affect the entire ecosystem and lead to changes that can be very serious. We have developed (see below) the consequences resulting from this in the context of the plant-insect relationship.

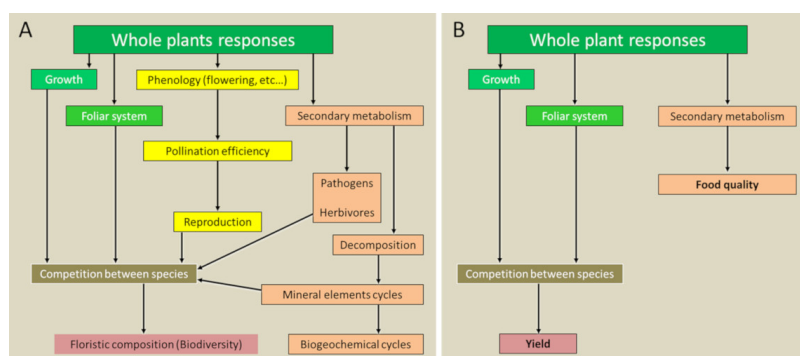

Figure 9. Representation of the consequences for natural (A) or anthropized (B) ecosystems of the effects of air pollution on plants. [Source: © J.P. Garrec]

Yield losses are more or less observable in anthropized ecosystems (large-scale cereal and oilseed crops, production forests). However, biomass is not necessarily reduced in natural ecosystems, as resistant species can occupy empty niches. Thus, softwoods are replaced by hardwoods in areas subject to fluorinated pollution. However, the resulting communities will be more

uniform, often with less stable ecosystems being less resistant to the various biotic or abiotic stresses they experience. In Figure 9, we have schematically represented the different consequences of the effects of air pollutants on vegetation in natural ecosystems compared to anthropized ecosystems.

Figure 10. Pine forest in Tramonto da Monte Sona (Etna, Sicily). [Source: © Photo Angelo Failla (CC BY-NC-SA 2.0), via Flickr]

In these communities, a number of individuals from sensitive populations are disappearing. But selective action can also occur on the most tolerant individuals or species that survive, resulting in the selection of a particular phenotype. For example, on the Etna's slopes, which is a particular source of air pollution by fluorine (HF), a pine forest is present, despite the tree's high sensitivity to this pollutant (Figure 10).

4.2. Impacts on humans

The impact of air pollution on plants in natural ecosystems can have direct consequences for humans and their health, mainly as a result of the consumption of contaminated plant products from these ecosystems (fungi, berries, fruits, etc.). Indirect consequences for humans following environmental degradation are also possible: risks of erosion or landslides, possibilities of flooding and modification of the water cycle and micro-climates with the disappearance of the vegetation cover, without forgetting the negative aesthetic effects linked to biodiversity losses such as the absence of trees for example.

But it is the impacts of air pollution on plants in human ecosystems (or agrosystems), summarized in the table below, that will most directly affect humans and their health through the contamination of many food chains.

Table. Summary of the effects of pollutants on plants and their consequences for humans

Target	Main pollutants	Effects on plants
Field crops: cereals and oilseeds	Ozone	Yes Loss of yield (5 to 10%)
Vegetable, fruit and wine growing	Heavy metals Organic compounds	No
Prairies	Ozone	Yes Loss of yield (5 to 10%)
Production forests	Ozone	Yes Loss of yield (5 to 10%)

5. Impacts on plant-insect relationships

In an ecosystem, vegetation constantly interacts with its entire environment. Air pollution, by modifying plant physiology and biochemistry, will have a decisive effect on these different interactions, and in particular on plant-insect interactions. The three key plant parameters that govern these interactions - recognition, nutritional qualities and defence systems - will be affected with varying degrees of consequences.

5.1. Disturbances in the location and recognition of plants by insects

Figure 11. Industrial mechanism of the peppered moth. This moth spends the day motionless on birch trunks, invisible to predatory birds (A, white typical shape). The black form, carbonaria (B), became the majority in polluted areas after the industrial revolution in the 19th century. [Source: Photos © Olaf Leillinger; License CC-BY-SA-2.5 & GNU FDL]

Air pollution often leads to a change in plant colour, which strongly influences the colour of associated insects. In England, in industrial areas, heavy air pollution led to the disappearance of lichens and the blackening of birch trunks in the 19th century. It was then found that the peppered moth (*Biston betularia*), a moth usually white with black spots, was found mostly in its mutated, much darker form (Figure 11). This is explained by the fact that dark butterflies, which are more difficult to spot, were better protected against bird predation than light-coloured individuals (see [The adaptation of organisms to their environment](#)). The same phenomenon was observed in Paris in the 1980s in the ailanthus silkworm (*Samias cynthia*), which dramatically evolved from light beige to very dark brown to adapt to its environment, following the pollution that blackened its food plant.

Air pollution also disrupts chemical communication between plants and insects. By acting indirectly on chemical communication substances (chemical mediators), certain pollutants such as ozone disturb plant-insect relations (e. g. recognition of spawning grounds):

via their physiological effects on plants, for example on the emission of terpenes limited by the closure of stomata;

by degrading or modifying the physico-chemical composition of chemical mediators, rendering them ineffective.

Finally, air pollution also causes changes in leaf recognition in insects. Pollutants such as ozone or CO₂, by promoting the production of cuticular waxes and thereby modifying the physico-chemical characteristics of leaf surfaces (see Focus [Between protection and defence: the plant cuticles](#)), have repercussions on the recognition of these by insects.

5.2. Changes in plant nutritional resources for insects

Air pollution induces the presence of external elements in or on plants that can have serious consequences on associated insects. The high accumulation in plant organs of toxic air pollutants such as heavy metals, arsenic, fluorine and certain plant protection products are often the cause of poisoning and mortality of phytophagous insects (in chewing insects and "sucking insects") and pollinating insects (bees, etc.).

In plants, air pollution - like many other stresses - causes qualitative and quantitative changes in primary and secondary metabolites. There is often an increase in concentrations of amino acids (proline), soluble proteins and sugars in the leaves, increasing their nutritional quality for some insects.

Pollutants such as SO₂ and NO_x, which increase sulfur and nitrogen concentrations in plants and improve their nutritional qualities, also have a positive effect on insects. This is particularly true for roadside and highway plants, which are important sources of NO_x. But on the other hand, the CO₂ pollution often present with NO_x leads to a decrease in nitrogen concentrations in the leaves following the modification of the carbon/nitrogen ratio.

5.3. Alterations in plant defences of against insects

Phenolic compounds and foliar cuticle, which constitute respectively a chemical defence system and a physical defence barrier for plants, are likely to be modified by pollutants:

Ozone and CO₂, like many other air pollutants that induce oxidative stress, increase concentrations of phenolic compounds in plants, thereby reducing the nutritional and taste qualities of leaves for insects.

At the same time, by promoting the production of cuticular waxes, both ozone and CO₂ improve the characteristics of the physical barrier represented by the cuticle (see Focus [Between protection and defence: the plant cuticles](#)).

Figure 12. Some examples of trophic interactions between plants and insects. A, bee foraging for a flower (Photo © John Severns, [Public domain], via Wikimedia Commons); B, firebug feeding on the fruit of a hibiscus (Photo © Calimo (Own work) [CC BY-SA 3.0], via Wikimedia Commons); C, aphid (Photo MedievalRich [CC-BY-SA-3.0], via Wikimedia Commons); D, caterpillar feeding on a leaf (Photo Daniel Mietchen (Own work)[CC0], via Wikimedia Commons); E, Mexican fly on a grapefruit (Photo Jack Dykinga, USDA, Bugwood.org, [CC BY 3.0], via Wikimedia Commons); F, Lonicera leaf miner (Photo Kenraiz Krzysztof Ziarnek (Own work) [CC BY-SA 4.0-3.0-2.5-2.5-2.0-1.0], via Wikimedia Commons).

Thus, in many examples, the impact of air pollutants on plants increases both their nutritional and their defensive qualities. The resulting positive or negative changes in plant-insect relationships will therefore depend on the combination of these two contradictory effects on the insect. However, since these relationships will also depend on the feeding pattern of the insect (mandibulate- or sucking-lapping type, piercing-sucking type, borer or miner type, Figure 12), it is difficult to define a universal model. However, *in situ*, it is an increase in insect populations on plants that is most commonly observed in polluted areas.

6. Messages to remember

Gaseous air pollutants enter plants through leaf stomata while particulate pollutants are captured by the micro-structure of leaf surfaces.

The phytotoxicity of air pollutants depends on their chemical nature.

The pollutants induce oxidative stress in the plant with the production of free radicals (hydroxyl radicals) and reactive oxygen derivatives (ROD) that cause damage in the leaf.

The plant uses processes such as stomatal closure to limit the absorption of the pollutant.

Some external factors can have a positive impact on the plant's response to air pollution. Thus, drought leads to the closure of stomata, which protects the plant.

Air pollution, by modifying plant physiology and biochemistry, has a decisive effect on ecosystems, including plant-insect interactions.

Nitrogen compounds are not very phytotoxic but have a strong impact on vegetation: a beneficial fertilizing effect in the first place and a negative impact in the long term by causing eutrophication of ecosystems.

90% of the yield losses due to air pollution in the plant world come from ozone.

While the various particulate pollutants have little or no impact on vegetation, they contaminate the food chains of humans and animals through the plants that are consumed.

Air pollution alters the nutritional qualities of plants used by plant insects.

Plant defences against insects are altered by air pollution.

[1] In the case of air pollution, we refer to ground-level ozone, a secondary pollutant formed in the lower layers of the atmosphere, near the earth's surface. This ozone is to be distinguished from ozone found at a fairly high concentration in the Earth's stratosphere, mainly at an altitude of between 15 and 20 km. By absorbing nearly 97% of the ultraviolet rays from the sun, stratospheric ozone forms a layer that protects living organisms from the dangers of UV radiation.

[17] In 1987, in Montreal, the main CFC-producing countries decided to stop producing CFCs. In Europe, CFCs have not been available on the market since 2000 and have had to be recovered and destroyed since 2002. To replace CFCs, manufacturers then adopted HFCs, which have been widely used but also have an environmental impact. The end of the use of HFCs was recorded in an agreement signed in Kigali (Rwanda) in 2016.

[18] Methyl bromide is one of the substances covered by the Montreal Protocol (1987). The production and placing on the market of methyl bromide has been banned since 2005, except for derogations for strictly regulated uses.
